#### ABSTRACT

**Objective:** To evaluate the association between self-esteem and anxiety in pregnant women admitted to a high-risk sector. **Methods:** Quantitative, cross-sectional, observational study. Data were collected through interviews with pregnant women admitted to the high-risk maternity ward, from April 1 to June 31, 2016. The sample totaled 112 women and was by convenience. **Results:** Of the women, 72.3% presented low self-esteem and significant correlation with educational level ( $p = 0.004$ ). The anxiety was 60.7% and the religion was the only variable with a significant association ( $p = 0.04$ ). There was no significant association ( $p > 0.05$ ) between the pattern of self-esteem and levels of anxiety for the fixed margin of error (5%). **Conclusion:** The impaired self-esteem was present in most of the women in this study, especially with low level of schooling. The anxiety was present in the majority of women, and there was an association between it and lack of religious practices. In this study, there was no significant correlation between self-esteem and anxiety. There is need to consider the two cases separately for a complete women's health promotion practice.

#### INTRODUCTION

Pregnancy involves numerous physical, hormonal, psychological and social changes, which may reflect, directly, in self-esteem and self-perception of the woman, in the

interaction between mother and child, the relations of the woman with her relatives and with her spouse (Osorio-Castaño et al., 2017). Among the changes present in the pregnancy-puerperal cycle, the psychological ones deserve notoriety since

they determine a good evolution in pregnancy. Among the disorders triggered in pregnant women, the Common Mental Disorder (CMD) presents a prevalence of 29.2% and is characterized by somatic symptoms of depression, irritability, forgetfulness, reduced ability of concentration, anxiety, fatigue, insomnia, difficulty in memory and concentration and complaints. It manifests as a mixture of somatic, anxious and depressive symptoms (Parreira *et al.*, 2017). Anxiety, in the gestational period, has been associated with several reasons, such as fetal distress, preterm birth, low birth weight and problems in the child's development. Other factors also corroborate, such as: demographic data (race, age, marital status, years of study, professional status, socioeconomic level), obstetric, psychological (woman's personal history, psychopathological history, personality characteristics, sexuality and desire to become pregnant), psychosocial (occurrence of significant life events and social support networks) and even cultural factors (Castro *et al.*, 2017). Pregnancy also interferes in the woman's self-esteem due to physical and emotional vulnerability that results from various physiological and anatomical changes that occur throughout the pregnancy cycle (Osorio-Castaño *et al.*, 2017). Self-esteem is the concept a person's has of him/herself, formed during the first childhood, through emotional experiences lived during this period. Over the years, this self-esteem formed has a great importance in the formation of personal relationships, including the establishment of the mother-child bond (Goyatá *et al.*, 2016). Considering the above, the study aims to identify the pattern of self-esteem and anxiety in pregnant women hospitalized in a high risk sector and assess its relations with the sociodemographic variables and the association between self-esteem and anxiety.

## METHODS

Cross-sectional, quantitative study, carried out in the maternity ward of a public hospital in the city of Recife, Pernambuco, Brazil. This institution is a reference in high-risk pregnant women's health care. The study was approved by the Research Ethics Committee (REC) of the Agamenon Magalhães Hospital (HAM) under the CAAE n.: 53579916.2.0000.5197 and opinion n.: 2.710.417. The participants received information on the protocol of the study and signed the Informed Consent Form (ICF). This study is part of the residency completion work (RCW) of the author: Liniker Scolfild Rodrigues da Silva. The data collection occurred through interviews with pregnant women admitted to the high-risk maternity ward in the period from April 1 to June 31, 2016. The sample included pregnant women aged 18 years and excluded: pregnant women suffering from some previous mental disorder and/or with hearing disabilities and illiterate pregnant women. The sample totaled 112 women and constitutes a convenience sample. The pregnant women were approached after admission to the high-risk sector. For the collection of demographic, clinical and obstetric data, a questionnaire was used, adapted to the population under study, which included the following data: age, marital status, education, socioeconomic, housing, dwelling, occupation, religion, gestational age, number of pregnancies, delivery route of previous pregnancies, if the pregnancy was desired and/or planned and reason for hospitalization in high risk. To evaluate the self-esteem, the Rosenberg's Self-Esteem Scale - RSES (1965) was used. This is internationally known and validated in 1989 and adapted to Brazil by Hutz in the year 2000 and aims to identify changes in self-esteem (Cogollo *et al.* 2015).

This scale is composed of 10 multiple-choice questions, with six related to "oneself", and four related to a "self-deprecating" view. The items are assessed on a Likert-type scale through four points distinguished between: "strongly agree" (4) "agree" (3) "disagree" (2), and "strongly disagree" (1). A high self-esteem is indicated by a high score. Regarding the score, this can vary from 10 to 40, based on the sum of the score given to the 10 sentences. A satisfactory self-esteem is defined as a score greater than or equal to 30 and unsatisfactory, with a score below 30 (Cogollo *et al.*, 2015). Next, the Beck Anxiety Inventory (BAI), or Beck Anxiety Scale (BAS), created by Aaron Beck (Gandini, 2007), and validated in Brazil by Cunha in the year 2001 (Araújo *et al.*, 2007), was applied. It is an instrument with a particularity, as it is ideal to be applied to psychiatric patients. It consists of a self-report scale proposed by Beck to discern the common symptoms of anxiety. The total score is the sum of the scores (0 to 63) with 21 items in total, using the following questions: "Not at all"; "Mildly (it did not bother me much)"; "Moderately (it was not pleasant at times)"; and "Severely (it bothered me a lot)". And the results can be: 0 to 9 - minimum anxiety; 10 to 16 - mild anxiety; 17 to 29 - moderate anxiety; and 30 to 63 - severe anxiety (Godoy *et al.*, 2002). There were descriptive analyses of the demographic, clinical, obstetric and psychological variables, calculating the mean and standard deviation for continuous variables, and describing the absolute and relative frequencies for categorical variables. Later, T tests were performed (for continuous variables) and Chi-square test (for nominal variables) to compare the demographic and obstetric variables. To verify the correlation between self-esteem and anxiety, Pearson's chi-square test or the Fisher's exact test was used when the condition to use the Chi-square test was not verified. The margin of error used in the decision of the statistical tests was 5.0%. The program used for data typing and statistical calculations was SPSS version 23.0, being presented as tables.

## RESULTS

About the obstetric conditions of the pregnant women interviewed, in relation to the gestational age, more than half (53.6%) of them were early preterm, followed by 31.2% late preterm, 14.3% early term and only one was term; regarding the number of pregnancies, the largest percentage corresponded to trigravida (29.5%), the smallest, to multigravida (20.5%) and primigravida and bigravida had 25.0% each; the majority (71.4%) had not aborted and, among those who underwent abortion (22.3%), 65.2% fell in unwanted/unplanned pregnancy. Among the reasons that led to hospitalization in high-risk sector, the most frequent were: single topical preterm pregnancy (63.4%), Urinary Tract Infection (UTI) (25.9%), Gestational Hypertension (21.4%), Premature Labor (PL) (15.2%), Gestational Diabetes Mellitus (12.5%), single topical term pregnancy (8.9%), pyelonephritis (8.9%) and Premature Rupture of Membranes (PRM) (8.9%). There may have happened more than one reason for hospitalization. Table 1 shows that most pregnant women (72.3%) had poor self-esteem. Regarding anxiety, (39.3%), 35.7% had mild to moderate anxiety, 16.1% moderate to severe and 8.9% severe anxiety. Table 2 reveals that the variability can be considered reduced on Rosenberg's scales and subscales, since the values of standard deviations are below 1/3 of the corresponding means, whereas in the anxiety scale, the variability was high since the standard deviation was over half the mean value.

Table 3 presents the association between sociodemographic variables and self-esteem. Schooling was the only variable with significant association with self-esteem ( $p = 0.004$ ), uncovering that poor self-esteem reduces the measure as the degree of schooling increases. Furthermore, 66.5% of the interviewees are from 18 to 30 years and women aged 26 to 30 years tend to show greater dissatisfaction. The age of pregnant women in this sample was not significant in the definition of scores of self-esteem.

Table 4 unveils the association between anxiety scale and sociodemographic variables. According to the analyzed data, religion was the only variable with a significant association with the anxiety scale ( $p=0.04$ ) and, for that variable, the percentage with anxiety was higher among those who had no religion (87.5%), and ranged from 52.6% to 61.5% among evangelical and catholic women. Table 5 shows the association between the degrees of anxiety and level of self-esteem. There was no significant association.

## DISCUSSION

Pregnancy is a moment that results in changes in the physical, social and emotional aspects of the woman, and the decreased self-esteem is associated with several factors, such as self-perception, process of adaptation to the body, hormonal changes, in the domestic routine, in the relationship with the spouse and family. The occurrence of implications in self-esteem can affect the proper development of the fetus and, later, the life of the mother and the child (Silva *et al.*, 2010). Santos *et al.*, (2015), emphasize that high-risk pregnancy constitutes a disturbing experience because of its risks for the child and mother and their possible psychological and physical impairments. In this sense, when observing the levels of anxiety and low self-esteem in high-risk pregnant women, 60.7% of them present with some level of anxiety and 72.3% have poor self-esteem. In this study, 65.2% of the interviewees reported experiencing an unwanted/unplanned pregnancy. According to Silva *et al.*, (2017), the non-occurrence of family planning allied to the propensity to triggering emotional disorders and other associated factors, can be triggering factors

for the development of mental disorders in pregnant women, generating major impacts on the mental health of those women. In relation to schooling, Santos *et al.*, (2015), affirm that there is an unsatisfactory relationship between low schooling and self-esteem. In this study, among 25 women who have not completed elementary education, 96% have poor self-esteem. Among those who have completed elementary education, only 25% are satisfied with their self-esteem and, among 36 women who attended high school and college, 61% are not satisfied with their self-esteem. Moreover, according to Santos *et al.* (2016), the pregnant women's family income can directly influence their self-esteem. According to the findings of this research, among all women with unsatisfactory self-esteem, 51.85% of them survive with one monthly minimum wage. Considering occupation variable, Maçola *et al.*, (2010), bring, in their research, that there was no significant relationship between having or not an employment and (un)satisfactory self-esteem. However, the need to talk about the activities performed demonstrated that the women who worked out-of-home had a certain apprehension about the new

life style and triple working hours, whereas the women who worked as “housekeepers” felt less apprehensive. In the present study, 77.6% of employed women and 61.1% of those unemployed feel dissatisfied with the self-esteem, which agrees with the previous survey and may suggest that unsatisfactory self-esteem is beyond having or not an occupation. Comparing the pregnant women who had a religion and those who had not, the non-practitioners have a higher rate of unsatisfactory self-esteem. Joshua *et al.* (2008), in their studies, showed that the proportion of pregnant women with no religion obtained a self-esteem significantly less satisfactory. In studies involving assistance to the pregnant woman’s health, the biopsychological disorders are recurrent throughout the pregnancy-puerperium period, including anxiety. Thus, the changes in the emotional spheres should receive due attention, as well as clinical manifestations, once they endanger the pregnant woman’s health and quality of life (Medeiros, 2016). Araújo *et al.*, (2007), show that most of their interviewees had low income, constituting potential risk factors for developing anxiety in pregnancy, and add that the family income may have a negative influence on the pregnancy, being a great stress factor. Such analysis is highlighted in the findings of the present study, which show that 72.2% of the respondents received less than one minimum wage and developed anxiety in pregnancy. In relation to marital status, in the present study, 68.4% of the interviewees have a stable union or are married and stated having developed anxious symptoms in pregnancy. Silva *et al.* (2015) confirm this finding, since they evidenced a greater frequency of pregnant women married or living with the partner with anxious symptoms (82.8%). As for the variable occupation, the same authors reveal that most pregnant women exercised labor activity (49.3%), which differs from the findings of this study, in which 69.4% of the interviewees reported having no occupation. The occupation, as well as family income, can provide perception of balance for the pregnant woman, since the existence of a wage decreases the concerns regarding this period of preparation for the birth of the child (Silva *et al.*, 2015). Low self-esteem, history of psychiatric diseases, postpartum depression, anxiety during pregnancy, stress, expectations related to motherhood, rejection of pregnancy, the aid provided during delivery, feeling of inability to take care of the child and other factors reveal themselves as the main factors that affect the quality of life of the mother, as well as of the newborn (Gawron *et al.*, 2015). Table 05 unveils that the correlation of the applied scales assists in understanding the incidence of anxiety levels and its implications in women’s self-esteem. In their studies, Silva *et al.*, (2010), show that the self-esteem in pregnant women is associated with changes in their mental status, and affirm that pregnant women with lower self-esteem had a higher probability of developing mental disorders, but the studies that address this issue are still scarce. Notably, the aim of this study was to compare the results of the assessment of anxiety (Beck) with the results of self-esteem (Rosenberg), revealing a statistically significant correlation between the two scales evaluated, since the p value is 0.503, i.e.,  $p > 0.5$ . Since there was no significance, there was no possibility of proving, through scientific researches, studies that resemble this finding.

## Conclusion

Self-esteem and anxiety are conditions that must be preserved during pregnancy. The present study unveiled that sociodemographic and obstetric factors can potentially

interfere with the quality of pregnancy and the lives of those women. Self-esteem is related to the self-acceptance or self-rejection, and this set of perceptions of oneself makes these pregnant women to know themselves and know how to deal with new situations, as is the case of pregnancy, even with the influences of culture, religion, beliefs, and/or experiences. Self-esteem favors the mental, emotional and physical health of pregnant women, as well as contributes to interpersonal relationships and acceptance of the pregnancy, since this psychological imbalance may cause serious health problems, including anxiety. Nevertheless, the present study could not make a significant relationship between anxiety and self-esteem. This suggests the separate screening of signs and symptoms of each one, based on the socioeconomic, cultural and epidemiological profile of the studied population, in order to promote actions of health promotion and disease prevention, through activities that raise awareness and carry information to women about the studied topics. A qualified assistance in Basic Care (BC), through the Family Health Strategy (FHS), focusing on care longitudinality and comprehensiveness, since before the pre-natal consultations, until the puerperium, is crucial to approach and reach the public of study and the strategies proposed in this study. Furthermore, the need for monitoring by the multiprofessional team, its constant updating about its target audience, in possession of continued education about the studied topics, is evident for pregnant women a healthier experience pregnancy, more humane, satisfactory and with a greater reduction of possible damage.
